Abstract
Reconstruction surgery after the excision of musculoskeletal tumors has advanced greatly in the last few decades. After resection of a large piece of bone, limb reconstruction (when is necessary) can be easily achieved with mechanical reconstruction with metallic prosthesis, or biological reconstruction with bone. The use of bone in reconstructive orthopedic surgery is to repair skeletal defects and accelerate bone healing. Bone grafts can be used to achieve this. Those can be allografts and autografts.

The standard in bone grafting consists of tissue harvested from the patient, autograft, usually from the iliac crest or distal femur and tibia. Allografts are taken from donors or cadavers and they serve as alternatives to autograft in bone reconstruction. In our case, the patients were treated with wide resection of the bone segment. The defect was reconstructed with intercalary bone and osteosynthesis was made with locking plates. A cadaveric graft was used. Autogenous bone is generally used as an optimal graft because it integrates faster and with fewer complications. Allogeneous bone can carry the risk of viral infection for the recipient. Anyhow, allografts can serve as the only therapeutic options, besides endoprostheses devices for large size reconstruction.

Keywords: allograft, transplantation, bony reconstruction, cadaveric, donor, metallic prosthesis;

Introduction:

With the latest development of neoadjuvant chemotherapy, radiotherapy and targeted therapy in the clinical treatment of malignant bony tumors, limb salvage surgery has become the most important surgical method for malignant bone tumors.

Limb salvage surgery includes two key techniques: radical resection of tumors and effective reconstruction of bone defects.[1]

The reconstruction of a large bony defect, especially after tumor resection still remains a fundamental challenge for an orthopedic surgeon. That requires an additional treatment with bone graft materials in order to restore the preexisting function.[2]

A successful bone augmentation should include an osteoconductive and osteo-inductive stimulus, should provide sufficient initial mechanical stability, and should enable osteogenesis, Osseo-integration and proper vascularity. [3]

The use of bone in reconstructive orthopedics is to repair the skeletal defect and accelerate bone healing. Bone grafts serve a combined mechanical and biologic function. [4]

After resection of a large piece of bone, reconstruction of the limb when it is needed, can be achieved with metallic implants, such as prosthesis, or with biological reconstruction with bone. [6]

We present three cases with malignant or aggressive bone tumors treated surgically with wide resection of the bone tumor and reconstruction of the bone defect with frozen cadaveric allograft. [7]
Case Reports.

**Figure 1.** A 62-year-old male with angiosarcoma of distal left tibia. (A) (B) Preoperatively performed X-ray of the affected bone. (C) Whole body bone scan done with Tc99m. (D) (E) (F) CT scan with multiple small slices. Wide resection of 6 cm long tibial diaphysis segment was made. The defect was reconstructed with intercalary tibial bone allograft and was fixed with two locking plates, thus enabling early mobilization.
Figure 1. Whole body bone scan done with Tc99m. (A) Resection of the bone. (B) Measuring the length of the defect. (C) (D) CT scan with multiple small slices. (E) (F) X-ray was made 2-nd postoperative day.

Figure 2. Intraoperative samples. (A) Resection of the bone. (B) Measuring the length of the defect. (C) (D) Implantation of a bone from allograft. Osteosynthesis the allograft material with two locking plates. (E) (F) X-ray was made 2-nd postoperative day.
Figure 3. A 17-year-old male with aggressive giant cell tumor of right radial bone. (A) (B) X-ray of the distal radius and ulna, which revealed an aggressive osteolysis of the right radial bone in her distal part. (C) (D) Distal radius with 7 cm length, including distal radial articular surface was resected due to joint invasion and fibular cadaveric graft was used. Because the lesion went through the articular surface, radiocarpal joint arthrodesis was performed. (E) (F) X-ray 2nd postoperative day, revealing good position of the osteosynthesis material.
Figure 4. (A) (B) (C) (D) (E) An X-ray and Ct of a 19-year-old female revealed Ewing sarcoma of the proximal part of the right femur, invading the intertrochanteric region and proximal diaphysis.
Cryopreservation, however, this cartilage degenerates faster over time and leads to degenerative joint disease. Allografts can fail due to lack of adequate vascularization, that can contribute to inner graft necrosis. [11]

Allogeneic bone grafts can also cause immunogenic reactions. Possible complications include: nonunion, infection, resorption and fracture. In a study of 20 patients, treated by resection and osteoarticular allograft application, Ogilvie et al. found high rate of adverse events (70%) and allograft removal (60%) in patients followed for at least 10 years. According to them, although there is high rate of complications and susceptibility to degenerative bone disease as a late complication that threatens function of the graft, there is still a role of osteoarticular allografts in complex reconstructions after tumor surgery. [5, 12]

Another large study of 398 patients treated with femoral or tibial allografts for low grade sarcomas or high-grade sarcomas responsive to neoadjuvant hemotherapy, showed that risk of allograft removal, joint replacement, or amputation was 36% at 5 years, 40% at 10 years, and 44% at 20 years. In this series, fractures occurred in 15%, infection in 14%, nonunion in 12% and tumor recurrence

**Discussion:**

The standard in bone grafting consists of tissue, harvested from the patient, or autograft, usually the iliac crest or distal femur and proximal tibia. [8] Autologous bone is generally considered as an optimal graft, because it integrates faster, with less complications than any other material. However, autograft sources are limited. For large bone defects and extensive reconstructions, allograft tissue or endoprosthesis devices are therapeutic options, both alone or as a combination. [9] Both techniques carry different advantages and risks for potential complications. Which serves as a better choice?

Cadaveric allograft transplants can aid in reconstruction of large bone defects, including osteoarticular segments by preserving joint function to the largest extent by maintaining articular cartilage and ligaments, and even preserving adjacent growth plates in adolescent patients. [10] There are studies that show that articular cartilage remains viable after cryopreservation, however this cartilage degenerates faster

**Figure 5.** (A) (B) (C) (D) Resection of proximal femur, application of femoral diaphysis allograft and hip joint endoprosthesis, which allowed for early patient mobilization.
in 7% of the patients. The highest grade of graft removal due to complications was observed in the group of tibial osteoarticular allografts. [13]

In a study of 90 patients treated for primary malignant bone tumors by reconstruction with non-vascularized autograft, allograft, and recycled frozen autograft, Wisanuyotin et al. found that there was no difference in functional outcome or complications between the three groups. They recommend that recycled bone should be used for osteoblastic lesions and for extensive osteolytic lesions, the allograft or autograft should be method of choice. [4]

Period of highest risk is the first 2 years, as an early complication, and late complications are also being described. In our study, we present cases with short follow up, therefore we cannot analyze late complications of this procedure. [2]

Conclusion:

Bone tumors should be diagnosed and treated in referral centers by a multidisciplinary team including pathologists, radiologists, orthopedic surgeons and oncologists. There is no prevention. Early diagnosis and adequate treatment are only hope for good outcome.[2]

Biological reconstructions with massive bone allografts are very useful after resection of certain malignant extremity bone tumors. The surgical techniques and method of treatment presented in this report will allow a better functional outcome and quality of life of treated patients. [2]

Our initial experience evokes the obvious advantage of using the allograft for treating lower extremity diaphyseal defect bony reconstruction after tumor resection, but following things should be taken under consideration: [2, 3]

- Precise preparation of allograft;
- Tumor resection for achieving good oncological prognosis post-operative;
- Stable internal fixation;
- Increased surface for bone healing and to prevent bone resorption;
- Adequate soft-tissue coverage;
- Minimizing the risk of post-operative infection and wound dehiscence.

Author Contributions

RD. conceived and designed the analysis, collected the data, treatment of all the patients in the article, observed the patients, contributed the data and analyses tools, performed the analysis and Interpretations, literature search, wrote the paper, other contributions (take the pictures), supervisor of the project, critical reviewer. IH comprehended and designed the analysis, treatment of all the patients in the article, contributed the data and analyses tools, performed the analysis, wrote the paper, critical reviewer. MM conceived and designed the analysis, collected the data, treatment of all the patients in the article, wrote the paper, other contributions (take the pictures), critical reviewer, literature search. SK, KGj considered and designed the analysis, collected the data, treatment of all the patients in the article, wrote the paper, other contributions (take the pictures), critical reviewer, literature search.
