Abstract
Ovarian tumours are commonly seen in reproductive age group in women. However, when they occur at extremes of age, the suspicion of malignancy increases. The detection of dermoid cyst at 56 years of age is uncommon, hence proper imaging with CA-125 level monitoring is essential. Awareness of benign tumours or rare possibility of malignant transformation in such age is mandatory for surveillance management or planning the surgical procedure.

Keywords: postmenopausal woman, malignancy, mature cystic teratoma

Background:
The adnexal mass in a postmenopausal patient poses an important diagnostic and management dilemma for primary care providers and gynaecologists. Postmenopausal women are at a significantly increased risk of gynaecologic malignancy; yet even in this population most adnexal masses are benign [1]. Mature cystic teratoma is the most common type of ovarian germ cell tumour. It constitutes 20-30% of all ovarian tumours [2]. It is mostly seen in women younger than 40 years old and is seldom seen in postmenopausal women. They are bilateral in 10-15%. Malignancy incidence is low (1-2%) [3]. The incidence of malignancy in “adnexal mass increases with age, and approximately 30% are malignant in postmenopausal females” [4]. It can have an unusual age presentation at 65 years with benign nature [5]. Pelvic ultrasound remains the mainstay for evaluation of adnexal masses in premenopausal patients. If ultrasound findings are indeterminate, magnetic resonance imaging (MRI) is the next imaging modality of choice [6]. Tumour markers and imaging can help in the evaluation of adnexal mass in postmenopausal women [1]. For adnexal masses that are highly suspicious for cancer, women should be referred to a gynaecologic oncologist and facility for optimal care [1]. Optimal management of an asymptomatic adnexal mass allows continued surveillance, it is indicated if the suspicion of malignancy is low, but it has not been completely excluded. Surveillance usually includes serial pelvic ultrasounds and/or measurement of serum tumour markers surveillance of women [7]. Surgery is recommended for any women with increasing morphologic complexity or a rising CA-125 [8].

Case presentation:
A 59 years old postmenopausal female presented with history of dysuria and frequency of micturition for few months. No history of renal disease or calculi. Recently complains of left iliac pain radiating to back with persistent frequency of micturition. On abdominal examination, it was soft, no organomegaly and no palpable masses felt with stable vital signs. A pelvi-abdominal ultrasound was requested and revealed a well-defined echogenic left adnexal mass measuring 7x7 cm with central hypo-echogenicity and fat-fluid level, no internal vascularity was seen by colour Doppler ultrasound, suggesting benign nature of the lesion. No ascites or lymph nodes were seen. The patient is referred to

the emergency for gynaecological assessment and further imaging recommendation. MRI was highly recommended to exclude neoplastic lesions. CA-125 (tumour marker) = 9.7 U/ml (high normal=35 U/ml). Gynaecologic Cytology report (cervical liquid specimen) was negative for intraepithelial lesion or malignancy. MRI pelvis showed a large cystic lesion of 9 x 7 x 7 cm in the left adnexa with the left ovary not seen separately. (figure 1-7). No enhancement is seen with fat intensity in all sequences suggesting left ovarian dermoid (mature cystic teratoma). The patient went through a laparotomy (total abdominal hysterectomy with bilateral salpingo-oophorectomy, omental biopsy and peritoneal wash that revealed histopathological evidence of a left ovarian mature cystic teratoma.

Discussion:

An “adnexal mass” is a common specimen encountered in the daily pathology practice. Although most are benign, the incidence of malignancy increases with age, and approximately 30% are malignant in postmenopausal females [6]. Gynaecologists must differentiate between benign and malignant adnexal masses. The evidence supporting to the speciality care of a gynaecologic oncologist based on the physical examination, imaging studies, family history, and CA 125 determination [9].

In our case, we started with transvaginal Ultrasound and the lesion was indeterminate, so MRI was recommended, and the patient was referred. The tertiary care hospital followed the guidelines for referral of patient with adnexal mass study done by Gostout BS & Brewer MA on 2006 [9] and CA-125 was done, followed by MRI. According to a study that mentioned RMI (The score incorporates the patient’s menopausal status (M), ultrasound features of the lesion (U) was the best method for discrimination between BOTs (borderline ovarian tumours) and benign adnexal masses and was more accurate than the other parameters [10]. In our case, the RMI (RMI = U x M x CA-125 (U/ml) = 0 x 3 x 9.7 =0) results are (0) < 25 and our patient is categorized as “low risk” showing benign looking in all imaging modalities and CA-125 is low normal with no evidence of malignancies or metastases. The management of an adnexal mass depends upon the type of mass, urgency of the presentation, and degree of suspicion that the mass is malignant [7]. Low risk patients as in our study, for most women with a benign looking ovarian lesion and no other findings suggestive of malignancy, the study suggested surveillance rather than surgery [7]. However, the larger the mass, the less certain the sonologist can be about the content of the mass. Finally, a certain subset of these masses will continue to grow so one would rather remove them when they are within range for laparoscopic management [7]. In our case, the patient started to be symptomatic in the last few months with a large size of the ovarian mass so, the gynaecology oncolgist decided to go through a laparotomy: total abdominal hysterectomy, bilateral salpingo-ophorectomy, omental biopsy and peritoneal wash and the pathology report revealed a left ovarian mature cystic teratoma.

Conclusion:

Mature cystic teratoma is generally seen in reproductive age group; however, rare cases may occur in prepuberty age group to women in postmenopausal age group. Although the rate of malignant transformation is only 1% in patients with mature cystic teratoma, this may be more commonly seen in those patients with extremes of age.
